Expert Testimony

A B S T R A C T

This study aimed to point out the contribution of the frontal and maxillary sinuses for Forensic Sciences, specifically in Forensic Dentistry. For this, a review was performed with 30 articles comprised in the period 2003–2014, about the application of the frontal and maxillary sinuses for human identification and sex determination, using the search words: Frontal Sinus, Maxillary Sinus, Human Identification, and Sex Differences. It was observed that the frontal and maxillary sinuses are useful for human identification. In relation to sex determination, there is no agreement about the applicability of the frontal sinus, although authors suggest that further studies should be performed to verify if it can be employed as an auxiliary method; but regarding the analysis of the maxillary sinus, this has shown satisfactory results. Thus, It is possible to conclude that the frontal and maxillary sinuses provide important information to the forensic context in cases involving human identification and, in the case of the maxillary sinus, allow the sex determination.

1. Introduction

The identification is a systematic and organized process, which primary function is to establish the identity. For this purpose, various methods have been applied [1,2]. In the Forensic Sciences, different methods have been developed for human identification based on comparisons between ante and post mortem data [1,3].

The fingerprint is an accurate identifying method, widely applied; however, in some cases, the collection becomes difficult or even impossible, such as in decomposed, fragmented or charred corpses [1,3–7]. Regarding DNA, although their techniques are accurate and propitiate reliable results, the method is time consuming and requires laboratory infrastructure, besides being impossible if the remains are badly degraded or exposed to environmental conditions [2,6–8].

In cases where these traditional methods are unfeasible, there is the study of anthropometric characteristics, as a secondary method in human identification, and, this method is reliable and essential to guide the identification procedure [8,9] and still gains importance when combined with Forensic Dentistry [1,3,5,7,8,10,11], can avail of information able to set the identity [7,8,12–14] from comparative analysis of anatomical variations [1,6,13,15].

An example of this analysis is the identification using the frontal and maxillary sinuses. The frontal sinus has become quite solidly in forensic identification, and, this method is reliable and essential to guide the identification procedure [8,9] and still gains importance when combined with Forensic Dentistry [1,3,5,7,8,10,11], can avail of information able to set the identity [7,8,12–14] from comparative analysis of anatomical variations [1,6,13,15].

An example of this analysis is the identification using the frontal and maxillary sinuses. The frontal sinus has become quite solidly in the literature as a safe method [1,4,8,12,16] for comparative radiographic studies to get the identification [1,2,4,8,12,14,16–22]. Regarding the use of the maxillary sinus, their characteristics...

</tbody>
</table>
provide important insights that enable the forensic identification [9,23–25].

This literature review aimed to evaluate the contribution of the analysis of the frontal and maxillary sinuses for Forensic Sciences in human identification and sex determination.

2. Material and methods

This review studied articles comprised between 2003 and 2014, involving the last decade of published works, about the application of the frontal and maxillary sinuses for human identification and sex determination, from the Forensic point of view.

The keywords used, by DeCS (Descriptors in Health Sciences), were Frontal Sinus, Maxillary Sinus, Human Identification, Sex Differences. The databases Pubmed and Scielo were used in this research.

The inclusion criteria were papers that used maxillary and/or frontal sinuses in human identification and sex determination purposes. The selected papers were published in English or Portuguese and the article types were theses available on the internet databases including literature reviews, case reports and research papers.

3. Results

47 articles were found. and the analysis of each one showed that 30 articles were specifically about human identification or sex determination by the frontal and maxillary sinuses; 9 articles do not had relation with the specifically theme (sex determination or human identification), but were related in references and were used in other parts of this paper (as introduction and discussion); about the remaining 8 articles, 2 articles were excluded because of the publication language that was Chinese, and the 6 others reported technical aspects of the procedures or could not be correlated with the Forensic Dentistry context and it were excluded. Table 1 providing information such as author, year of publication, type of publication (case report, original research article, review, etc.), power (number of cases being examined), modality used (x-rays, CT, other), the anatomical region examined (frontal or maxillary sinus or both), analyzed implication and conclusion.

4. Discussion

In human identification, there are cases of wide body degradation, such as charred, skeletonized, and in advanced stages of decomposition [2,4–6,8,10,22,28,35] and, in these cases, the study of anthropometric characteristics and anatomical peculiarities get fundamental importance, which enables the identity [5,6,8,9,15].

The analysis of the frontal sinuses has become quite solidly in the literature as a secure method for comparative radiographic studies that promote human identification [1,2,4,8,12,14,16–22], due to the fact these sinuses are unique to each individual [26,27,29], even among monozygotic twins [2].

The uniqueness of frontal sinus is justified by the large inter-individual variation [1,4,6,8,12,14,22,27] as the size, shape, symmetry, outer edges, presence and number of septa [12]; therefore this analysis meets the requirements of uniqueness, permanence, immutability [1], providing technical and scientific information to be used in forensic identification [8]. Comparisons of data provided by the specifics of the frontal sinuses were feasible in most cases, with the remaining usually prevented by positioning the influence of radiographic examination, as well as the quality of the radiographs [17].

In human identification the uniqueness of frontal sinus is advantageous, but to sex determination this large individual variation inhibit the use [21,22,32] and, despite studies on the morphological analysis of the frontal sinuses like an ineligible method for this purpose [21,27,35], other studies indicate its use as an auxiliary method [2,22,28,32] and there are authors who claim more research is needed regarding to obtain a conclusion [22].

When it comes to the maxillary sinuses, its high specificity makes reliable the method for this parameter of human identification [9,23–25]. However, in the literature there are few studies that used this method, when compared to work performed using the frontal sinuses.

In relation to sex determination, it appears as valid by the structural comparison of the maxillary sinuses [9,23,30,31,33,34,36–38] and data presented in the literature clearly show that the volume and dimensions of the maxillary sinuses shown to be significantly higher in males than in females [9,33,34,36,37], except in children until six years of age [36]. The analysis of the maxillary sinus act as a helper method in sex determination [9,31,33,34,37,38]. However, there is no wider literature that analyses sex determination and therefore it is suggested that further studies about this subject are conducted in order to facilitate this determination [9].

It is evident that in cases where no one has the possibility of applying traditional methods of identification, analysis of the frontal and maxillary sinuses is important. Possible disadvantages are the need for ante mortem materials available for the compare and the possibility of this material does not present good quality (for example, a panoramic radiograph showing the cut or distorted maxillary sinuses). About the drawbacks of the post mortem imaging techniques in forensic identification and sex determination, the compromised integrity of anatomical structures can hinder the technique, and it’s necessary trying to copy the conditions in life, for comparison. But the advantage is precisely the possibility of positioning the anatomical structure as it would be in life. In addition, the comparison of images is a completely viable method.

So, in a total of 30 papers presented in this review, 17 related the frontal sinus, 11 maxillary sinus and only 2 about both sinuses. About the methods of analysis of these paranasal sinuses, in the studies of the frontal sinus, 94.12% were based on radiographic images and only 5.88% were based on radiograph and computed tomography. Although in the studies of the maxillary sinuses, 36.36% used radiographic images and 63.64% used computed tomography. Regarding the articles that studied both frontal and maxillary sinuses, one half cited radiographs and the other half cited computed tomography.

In order of the forensic context, the subject of this study, the frontal sinus was associated in 70.59% to human identification, 23.53% to sex determination and only 5.88% to both purposes; in the studies with maxillary sinus, 72.73% were about sex determination, while 18.18% were about human identification and, 9.09% to both. The articles that studied the both sinuses, frontal and maxillary, were used to evaluated human identification. In this literature review, it were noted the trend of recent studies that use the frontal sinuses to sex determination, the same is observed for the maxillary sinuses, the studies focus on sex determination, and the most promising contribution mainly by computed tomography.

5. Conclusions

According to the literature review, is possible conclude that frontal and maxillary sinuses are useful tools for human identification. There is no agreement about the use of frontal sinus to sex
determination. In relation to the maxillary sinus, the application to sex determination is satisfactory.
